Big Bounce and inhomogeneities

Instituto de Estructura de la Materia, CSIC, Serrano 121-123, 28006 Madrid, Spain

The dynamics of an inhomogeneous universe is studied with the methods of Loop Quantum Cosmology as an example of the quantization of vacuum cosmological spacetimes containing gravitational waves (*Gowdy* spacetimes). The analysis performed at the effective level shows that: (*i*) The initial Big Bang singularity is replaced (as in the case of homogeneous cosmological models) by a Big Bounce, joining deterministically two large universes, (*ii*) the universe size at the bounce is at least of the same order of magnitude as that of the background homogeneous universe, (*iii*) for each gravitational wave mode, the difference in amplitude at very early and very late times has a vanishing statistical average when the bounce dynamics is strongly dominated by the inhomogeneities, whereas this average is positive when the dynamics is in a near-vacuum regime, so that statistically the inhomogeneities are amplified.

PACS numbers: 04.60.Pp, 98.80.Qc

The cosmological models based on classical General Relativity (GR) predict that the Big Bang singularity is the true beginning of the universe (boundary of the spacetime). This prediction, however, is believed not to be physical since, when one describes the early universe, GR is applied beyond its domain of validity. The quantum effects which dominate in this epoch are expected to resolve the singularity.

This issue was studied recently in the context of Loop Quantum Cosmology (LQC) [1] (see also [2]). The analysis of a simple model of a homogeneous and isotropic universe revealed surprising results [3]: a large classical expanding universe was preceded by a(n also large and classical) contracting one, which bounced (deterministically) and started to expand once the energy density of its matter content reached the Planck scale. The robustness of this result in more general situations was confirmed later [4, 5], including the case of anisotropic universes.

However, up to now these studies were mostly restricted to homogeneous spacetimes. Although a preliminary analysis of the effects of inhomogeneities was presented in [6], it was not known whether the modifications to the universe dynamics predicted by LQC survive in the presence of inhomogeneities. The possibility to answer this question arose when an LQC quantization scheme was formulated [7] for a class of cosmological spacetimes known as Gowdy universes [8]. These spacetimes, while still symmetric (they admit two spatial symmetries) include inhomogeneities that can be interpreted as (linearly polarized) gravitational waves, thus having local degrees of freedom. To describe them, a *hybrid* quantization scheme was applied: first the geometry was represented as the Fourier modes of a gravitational field (the linearly polarized wave) propagating in a homogeneous (Bianchi I) spacetime, next this Bianchi geometry was quantized using loop techniques, while for the gravitational wave modes standard Fock quantization methods were employed after introducing a suitable time-dependent scaling.

This construction paved the way to analyze the quantum dynamics of this inhomogeneous system; nonetheless the (field-like) complexity of the quantum configuration space makes the investigation of the genuine quantum evolution extremely difficult. This forces one to resort to *classical effective dynamics* [9, 10] – a classical theory which incorporates the main effects of spacetime discreteness and which has been shown to accurately mimic the quantum evolution in the cases where it has been tested on so far. Here, we apply this technique to analyze the quantum dynamical behavior of the Gowdy universe, answering in particular the following questions: (*i*) Does the Big Bounce persist in the presence of inhomogeneities? (*ii*) If the answer is in the affirmative, does the Big Bounce occur in similar conditions as in homogeneous models? (*iii*) And how does the structure of the gravitational wave modes change through the bounce?

Let us start by specifying in more detail the physical system which we consider here. The Gowdy universes are vacuum spacetimes with compact sections of constant time which, in spite of possessing considerable symmetry, still contain local degrees of freedom. Namely, these spacetimes possess two spatial isometries (two commuting spacelike Killing vectors). The Gowdy universes can be classified by their spatial topology [8]. The best studied case, on which we will concentrate, is that with the topology of a three-torus. This family of spacetimes provides a generalization of the homogeneous and anisotropic Kasner solution (for spatially flat topology) to include inhomogeneities which depend only on one spatial coordinate [11]. The spacetime inhomogeneities can be interpreted as gravitational waves propagating in an homogeneous background spacetime. We will consider exclusively the simplest case of linearly polarized waves, in which, after a suitable gauge fixing, all the inhomo-

geneities can be described by a single metric field and the metric adopts a diagonal form globally [7, 12]. That field can be expanded in Fourier series exploiting the periodicity in the only spatial coordinate on which it depends (this coordinate is cyclic for the studied topology). Strictly speaking, the inhomogeneities are determined by the nonzero modes of this decomposition. The rest of gravitational degrees of freedom of the system describe a homogeneous universe on which the gravitational waves propagate. Specifically, this is a Bianchi I spacetime with three-torus topology. The classical solutions of this cosmological model are known in exact form, and generically present a Big Bang singularity [13].

In order to quantize the system we follow the prescription used in [3], where the geometry (homogeneous) degrees of freedom were quantized via loop techniques, whereas for the "matter" ones (in this case the gravitational waves with a convenient field parametrization) standard (Schroedinger-like) methods were employed [12, 14]. The classical metric of the Bianchi I background in the adopted gauge is diagonal and determined by a triple of scale factors $a_i(t)$, where $i = 1, 2, 3$. In the formalism used for quantization, the phase space for this background is coordinatized by the $SU(2)$ (Ashtekar) connection $A^i_a = c^i \delta^a_i/(2\pi)$ and the densitized triads $E^i_a = p_i \delta^i_a/(4\pi^2)$ [15]. All the information about the system is encoded in the canonically conjugate variables (c^j, p_i), where $|p_i| = |\epsilon^{ijk}|a_j a_k/(8\pi)$ (ϵ^{ijk} is the completely antisymmetric unit tensor). Among the constraints that GR imposes on the system, only two are not automatically satisfied in the introduced gauge: the generator of S^1 translations on the inhomogeneous spatial direction (which affects exclusively the inhomogeneities described by the gravitational waves) and the spatial average of the Hamiltonian constraint. The latter can be written (up to a global constant) as $C = C_{\rm BI} + C_{\mathcal{F}}$ (where $C_{\rm BI}$ and $C_{\mathcal{F}}$ stand for the homogeneous background part and the "matter" correction encoding inhomogeneities, respectively). Specifically, the background part equals $C_{\rm BI} = \int_\Sigma {\rm d}^3x |\det(E)|^{-1/2} \epsilon^{abc} E^i_a E^j_b F_{ij\,c}$ where $F_{ij\,c}$ is the curvature (field strength) of the connection A^i_a.

The quantization methods parallel those of LQG [16]. In a first step, the constraint is ignored. The basic objects promoted to operators are the integrals of A^i_a along straight lines (holonomies) and those of E^a_i along square surfaces (fluxes). The resulting kinematical Hilbert space is a product $\mathcal{H}^{\rm kin} = \bigotimes_{i=1}^3 L^2(\bar{\mathbb{R}}_B, {\rm d}\mu_B) \otimes \mathcal{H}^{\rm kin}_{\mathcal{F}}$ where $\bar{\mathbb{R}}_B$ is a Bohr compactification of the real line and $\mathcal{H}^{\rm kin}_{\mathcal{F}}$ is a Hilbert space for the inhomogeneous degrees of freedom.

In the next step, the constraint C is promoted to (and solved as) a quantum operator. For this, $C_{\rm BI}$ has to be expressed in terms of holonomies and fluxes. In particular, the term $F_{ij\,c}$ entering $C_{\rm BI}$ is approximated by holonomies along small rectangular loops. Since the limit of the loop shrinking to zero does not exist in LQC, the rectangular loop is fixed (following [5]) by the requirement that its physical area equals the lowest nonzero eigenvalue of an area operator defined in LQG.

In the matter part of C, the degrees of freedom corresponding to gravitational wave modes (conveniently scaled by a time-dependent function) are represented via fields and momenta operators combined into creation and annihilation operators $(\hat{a}^\dagger_m, \hat{a}_m)$, $m = \pm 1, \pm 2, \ldots$, with standard commutation relations [12]. Therefore they form the standard Fock space $\mathcal{H}^{\rm kin}_{\mathcal{F}} = \mathcal{F}$.

The final quantum constraint $\hat{C}$ is a difference operator in all three coefficients p_i. In principle, one can find the (generalized) states annihilated by it, thus identifying the physical Hilbert space $\mathcal{H}^{\rm phy}$. This is indeed done in [7]. However, the representation of any state of physical interest is complicated to the extreme by the presence of an infinite number of degrees of freedom. To be able to extract interesting physics out of the system we appeal here to the so-called classical effective dynamics.

To derive this effective description (see [9] for details), one replaces the basic operators (holonomies and fluxes) in the Hamiltonian constraint by their expectation values, thus building back a classical Hamiltonian. Nonetheless, some aspects of the quantum theory are preserved by leaving the lengths of holonomies as determined by the minimal area requirement discussed above. The final form of the constraint (after proper densitization) reads

$$\begin{aligned} \mathcal{C}_G &= -\frac{2}{\gamma^2}(\Theta_1\Theta_2 + \Theta_1\Theta_3 + \Theta_2\Theta_3) \\ &+ \frac{G}{\gamma^2}(\Theta_2 + \Theta_3)^2 \frac{1}{|p_1|} H^\xi_{\rm int} + 32\pi^2 G |p_1| H^\xi_o, \qquad (1) \\ \Theta_i &= \frac{p_i\sqrt{|p_i|}}{M} \sin\Big(\frac{M c^i}{\sqrt{|p_i|}}\Big), \\ H^\xi_o &= \sum_{m=1}^{\infty} m \left[a^*_m a_m + a^*_{-m} a_{-m}\right], \\ H^\xi_{\rm int} &= \sum_{m=1}^{\infty} \frac{1}{m}[a^*_m a_m + a^*_{-m} a_{-m} + a^*_m a^*_{-m} + a_m a_{-m}]. \end{aligned}$$

Here, $i = 1$ denotes the direction in which there exists spatial dependence, G is Newton's constant and $M = \sqrt{2\sqrt{3}\pi\gamma} l_{\rm Pl}$ (γ is the Immirzi parameter and $l_{\rm Pl} = \sqrt{G\hbar}$ the Planck length). We note that the variables Θ_2 and Θ_3 are constants of motion, a fact which will considerably simplify the discussion of the effective dynamics.

Given this effective constraint, it is straightforward to derive the complete set of equations of motion, namely the Hamilton-Jacobi equations. By integration, one then obtains the time evolution of the system from any initial point in the phase space.

At this stage, it is worth pointing out that the above procedure does not take into account state-dependent parameters (like dispersions and higher-order quantities) which might significantly affect the dynamics. However, comparison of this effective approximation against the full quantum dynamics has been carried out in simpler models (i.e., homogeneous cosmologies with both massless and massive scalar fields), showing that the corrections arising from such parameters are negligible for the

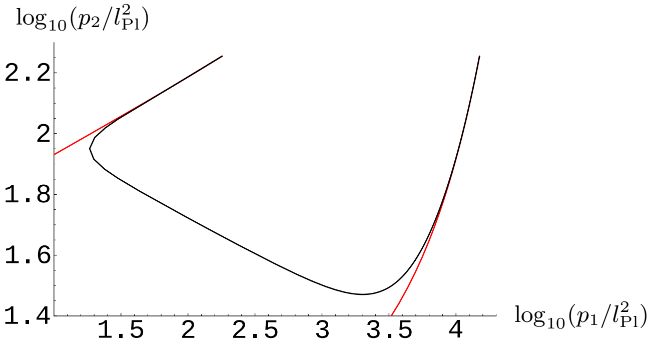

FIG. 1: A dynamical trajectory for the case $m_{\max} = 5$ (black) compared against the classical trajectories to which it converges in the distant future and past (red). Here, the value of H_o^ξ at the initial point ($p_1 = p_2 = 180 l_{\rm Pl}^2$) is $0.657\hbar$. The Immirzi parameter is set to its standard value, $\gamma = 0.2375\ldots$

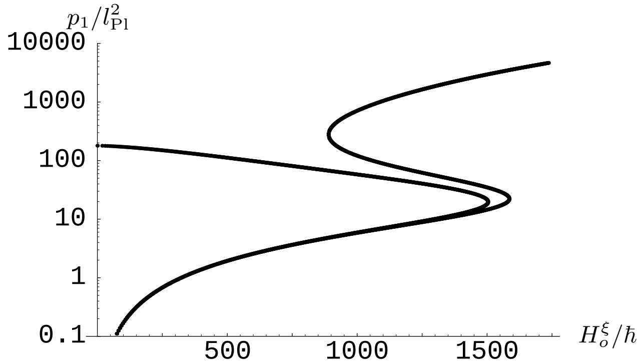

FIG. 2: The set of points satisfying relation (2) for the case $\Theta_2 = 3750 l_{\rm Pl}^2$, $\Theta_3 = 2500 l_{\rm Pl}^2$, and $H_{\rm int}^\xi / H_o^\xi = 2 \cdot 10^{-4}$. They form reflective boundaries for the dynamical trajectories.

states of physical interest (semiclassical at late times). This fact has been confirmed analytically in the simplest cosmological models [10]. Although the validity of the adopted effective description has not been tested in the model considered here, the commented results strongly support its ability to reproduce the behavior of the quantum system quite accurately.

We probed the dynamics of the effective system using Monte-Carlo methods. First, a large population (c.a. 10^4 points) of initial points was selected randomly in the phase space. In particular, apart from the restriction to satisfy the S^1-translation constraint, the values of a_m were generated randomly with Gaussian probability distribution (centered at the origin). Owing to technical limitations, simulations were restricted to a finite number of nonvanishing modes (specifically, the cases considered were $m \leq m_{\max} = 5, 10, 20$). To find the dynamical trajectories, the initial value problem consisting of the full set of equations of motion plus the chosen initial data was integrated via built-in adaptive methods of *Mathematica*. The analysis of the evolution was focused on two issues: (a) the existence of the bounce, and (b) the changes in the structure of the inhomogeneities through the bounce.

In order to address the first of these issues, the evolution of the inhomogeneous universe was compared against the evolution of its homogeneous counterpart, i.e. the universe determined by the same initial data for the homogeneous degrees of freedom and all inhomogeneities set to vanish. The dynamical trajectories obtained numerically confirm the presence of the bounce in all three spatial directions (see Fig. 1). Thus, the qualitative evolution picture stays the same as in homogeneous models. Besides, analytical studies show that the values of p_2 and p_3 when they bounce do not depend on the a_m's; hence the bounces in the homogeneous directions occur at the same values of p_i as for homogeneous universes. Finally, to check the behavior of the bounce in the inhomogeneous direction, more extensive analytical/numerical studies were performed. Exploiting the properties of the equations of motion, the investigation was carried out separately (and using different methods) in two domains: $\Theta_2\Theta_3 < 0$ and $\Theta_2\Theta_3 > 0$.

In the first case, it follows straightforwardly from (1) that the presence of inhomogeneities can only push the bounce away, that is, the bounce happens at a larger value of p_1. Indeed, recalling that $\dot{p}_1 = \{p_1, \mathcal{C}\}$ and taking into account that $\dot{p}_1 = 0$ at the bounce, one gets the constraint satisfied at that point,

$$|p_1|^3 = M^2 \frac{[F(p_1, \Theta_2, \Theta_3; H_o^\xi, H_{\rm int}^\xi) - \Theta_2\Theta_3]^2}{(\Theta_2 + \Theta_3)^2}, \qquad (2)$$

where F is a positive definite function such that $F(p_1, \Theta_2, \Theta_3; 0, 0) = 0$. The form of (2) implies immediately that, when $\Theta_2\Theta_3 < 0$, the contribution of F increases the value of p_1 (provided that Θ_2 and Θ_3 remain the same). As a consequence, the bounce in the inhomogeneous case always happens at larger universe sizes than in the homogeneous scenario.

The case $\Theta_2\Theta_3 > 0$ required a detailed numerical analysis, since now the two terms in brackets in the numerator of (2) have opposite signs. The behavior of the points satisfying (2) with respect to the magnitude of the inhomogeneities is shown in Fig. 2. A feature which is worth noting is the existence of the throat which allows, in principle, that the dynamical trajectory may go "down it" through an infinite sequence of bounces and recollapses, reaching the singularity. However this would be a critical trajectory (the set of initial data leading to such evolution has zero measure in the phase space), thus generically the universe will bounce at finite p_1. Besides, except perhaps for a very small subset of initial conditions (near the critical case), the bounce happens at a value of p_1 above certain bound, which is of similar order to the value found in the absence of inhomogeneities, p_1^o. The bound provided by our analysis is $\approx 0.13 p_1^o$.

Our study of the inhomogeneities was focused on discussing how their energy distribution changes through the bounce. This information is encoded in $|a_m|(t)$. Since, for large p_1, these quantities converge to well defined limits, it is particularly interesting to investigate the corresponding amount of asymptotic change for large universes, $\Delta|a_m| = \lim_{t\to+\infty}|a_m| - \lim_{t\to-\infty}|a_m|$. Actually, once the full set of initial data is specified, the evolution of the universe (including the inhomogeneities) is deterministic, so that the value of $\Delta|a_m|$ is fixed. Nonetheless, $\Delta|a_m|$ acquires a stochastic nature if one restricts its attention to energies instead of amplitudes for each of the gravitational wave modes, thus ignoring the initial phases of the a_m's. Within the space of possible trajectories, on the other hand, one can distinguish two differentiated regimes: (i) *inhomogeneity dominated,* for which the dynamics around the bounce is dominated by the content of gravitational waves, and (ii) *near-vacuum*, for which those waves introduce only small corrections to the vacuum Bianchi I dynamics around the bounce. In case (i) our numerical analysis of a large population of universes shows that, generically, $\Delta|a_m|$ is an antisymmetric function of the initial phase of a_m. Owing to this antisymmetry, the expectation value of $\Delta|a_m|$ (namely, its average over the dependence on initial phases) is ensured to vanish. In case (ii), a similar analysis shows that the antisymmetric behavior of $\Delta|a_m|$ is generically lost and its average becomes strictly positive. Therefore, in the near-vacuum case the quantum geometry effects around the bounce *pump energy* into the inhomogeneities.

It is worth noticing that, although our numerical analysis has been performed in all cases for a finite number of nonvanishing modes $m_{\max}$ (which plays the role of an UV cutoff on the gravitational waves) the results presented here do not change when $m_{\max}$ increases. As a consequence, they remain valid when the full Fock space of inhomogeneities is considered.

The results explained above constitute the first systematic analysis of the dynamics of inhomogeneous spacetimes in LQC. In particular, they provide further support to the bounce picture found earlier in homogeneous scenarios. The study reported here, and the methodology developed for it, paves the way for future analyses of the effective physics derived from LQG/LQC in more general spacetimes, opening an avenue, e.g., for the discussion of the effects of quantum geometry in the process of gravitational collapse and black hole formation.

Let us conclude clarifying that the presented analysis should not be treated as final. Firstly, our inhomogeneous system has been investigated by means of an effective theory which does not take into account many quantum effects. To confirm the reliability of the results, one ought to repeat the analysis in the full quantum setting. Secondly, the method of construction of the minimal area loop used to define the quantum constraint $\hat{C}$ is not unique. There exist several prescriptions for the construction, giving different quantitative predictions of the dynamics. Therefore, for robustness, an investigation of the system constructed with those other prescriptions is also desirable. Finally, one has to remember that, in the studied system, there is only one inhomogeneous direction; therefore the results regarding change of inhomogeneities through the bounce cannot be directly applied to the kind of models considered in observational cosmology. To obtain reliable results verifiable against observations, one has to extend the analysis to models which have the energy level degeneracy characteristic of a spherical harmonics decomposition. This is the task that we plan to accomplish in future work.
